Fermi liquids (FL) are ubiquitous in physics: helium, neutron matter, cold atoms, metals. In several bad metal superconductors, e.g. A-15, borocarbides, heavy fermions, the FL scattering time $\tau$ quadratic temperature dependence, i.e. $\rho = A T^2$, dominates the low temperature electrical resistivity $\rho$ above the superconducting transition temperature $T_c$. In the first place, we show empirically that there exists a relationship between $A$ and $T_c$ when both vary under an external parameter, such as pressure. The more resistive the compound the higher the $T_c$. Through the analysis of Landau theory of FL, we find that it is a general feature of FL, due to the fact that the scattering that is the main cause of $\tau$ is the same one that bounds the pairs that condensed at $T_c$. We devise a method that allows the determination of the coupling constant $\lambda$, which is validated through application to $^3$He-\textsuperscript{3}He's superfluid transitions and $\tau$‘s extracted from different properties. This method works for conventional superconductors, but fails with heavy fermions.
